best\_model

best\_model best\_model

## Description

Returns the best input models. The coefficient of the best model can be found with the poly\_model function

## Usage

```
best_model(
   inpt_datf,
   Degree,
   Coeff_v = NA,
   Powers = NA,
   Mth_symb,
   Numrtr_v = NA
```

## **Arguments**

inpt_datf	is the input dataframe, first column for the x values and second column for the y values
Degree	is a vector containing all the degrees. Each degree represents how many coefficients the model has.
Coeff_v	is a list containing the vector containing the coefficients for each model. The first value of each coefficient vector is always the constant, so it is not linked to any math symbol
Powers	is a list containing all the values associated with the math symbols of mth_symb list for each model. Because you can have multiple models in the function, so Powers is separated with the "-" separator between the different powers values for each model like in the examples
Mth_symb	is a list containing the vector of the different math symbols linked to the coefficients from the second value
Numrtr_v	is a list containing the different numerator values for each math symbol for each model, see examples

```
print(best_model(inpt_datf=data.frame(mtcars$wt, mtcars$mpg), Degree=c(2, 2), Coeff_v=c("
[1] 2
print(best_model(inpt_datf=data.frame(mtcars$wt, mtcars$mpg), Degree=c(2, 2), Coeff_v=c("
[1] 1
print(best_model(inpt_datf=data.frame(mtcars$wt, mtcars$mpg), Degree=c(2, 2), Coeff_v=c("
[1] 1
```

calcall 3

```
print(best_model(inpt_datf=data.frame(mtcars$wt, mtcars$mpg), Degree=c(2, 2), Coeff_v=c('
#' [1] 1
```

calcall

calcall

## **Description**

Takes a formula as a character as an input and makes the calculation. Accepts also variables, in this case the part of the formula that contains the variable wont be calculated, but the others part will be as usual.

## Usage

```
calcall(inpt)
```

## **Arguments**

inpt

is the input formula as a character

print (calcall(inpt="(log\_5\_Z-2-6+5)+-6+2"))

4 calcall\_var

```
[1] "(log_5_Z-3)-4"
print(calcall(inpt="m--2+-5"))
[1] "m-3"
print(calcall(inpt="(-2-6)+-6+2"))
[1] "-12"
print(calcall(inpt="m-6"))
[1] "m-6"
print(calcall(inpt="--6"))
```

calcall\_var

calcall\_var

#### **Description**

Does the same thing as calcall function but calculates the formula that have variables. The values of the variables have to be given in a list of vectors, see examples.

#### Usage

```
calcall_var(inpt, var_name_v, var_val_l)
```

## Arguments

is the input formula, with the variables

var\_name\_v is the vector that contains the variables name in the order of apparition in the formula. If the variable appears multiple times in the formula, it has to be specified in this vector, see examples.

var\_val\_l is the list containing the vectors containing the values of each variable, for each point you want to calculate. The vectors has to be given in the same order has the variable in var\_name\_v.

datf\_folder 5

datf\_folder

 $datf\_folder$ 

# Description

Folds a dataframe, see examples.

## Usage

```
datf_folder(inpt_datf)
```

# Arguments

inpt\_datf is the input dataframe

# Examples

print(datf\_folder(inpt\_datf = iris))

individual\_cloning individual\_cloning

## **Description**

Allow to generate individuals with the same label as those existig and having as values at variables, a value generated with a normal distribution having as parameters the mean for the variable A for the individual I and the same goes for the standard deviation, see examples.

#### Usage

```
individual_cloning(inpt_datf, col_vars = c(), label_var, hmn)
```

## **Arguments**

inpt_datf	is the input dataset as a dataframe
col_vars	is a vector containing the colnames or the column numbers of the variables
label_var	is a either the colnames or the column number of the label variable
hmn	is how many of new individual from the same label will be generated

```
datf <- iris
datf[, 5] <- as.character(datf[, 5])</pre>
datf <- individual_cloning(inpt_datf = datf, col_vars = c(1:4), label_var = 5, hmn = 3)</pre>
print(datf)
nrow(datf)
nrow(iris)

#### **Description**

Allow to increase the number of inividual from any label to a certain point based on the individual\_cloning function from the same package (Rmach)

#### Usage

```
individual_equalizer_min(inpt_datf, col_vars = c(), label_var, untl)
```

#### **Arguments**

is the input dataset as a dataframe

col\_vars

is a vector containing the column numbers of the variables

label\_var

is a either the column number of the label variable

unt1

is how many individual from the same label the dataset has to have, at minimum

# **Examples**

30

4.700000

3.200000

datf <- iris

```
datf[, 5] <- as.character(datf[, 5])</pre>
datf <- individual_equalizer_min(inpt_datf = datf, col_vars = c(1:4), label_var = 5, untl</pre>
print (datf)

individual\_route individual\_route

# Description

From a time serie, allow to get the most common route for each individual at a given depth (time - 1). Access the frequency value as an element from the output vector and the value itself (the path)

20 knn\_Rmach

as a name of its element, see examples.

#### Usage

```
individual_route(inpt_datf, col_target, id_col, untl_last = 2)
```

#### **Arguments**

inpt\_datf is the input time serie as a dataframe

col\_target is the column name or number that refers to the value of each individual

is the column name or number that refers to the individual (ids)

untl\_last is the depth value

## **Examples**

```
datf_{test} \leftarrow data.frame("id" = c(1, 1, 1, 2, 2, 3, 3, 3, 4, 4, 5, 5, 5, 5),
                         "city" = c("A", "C", "B", "B", "A", "C", "A", "C", "A", "C", "B"
print(individual_route(inpt_datf = datf_test,
                       col_target = "city",
                       id_col = "id",
                       untl_last = 2))
AC CA BA
 2 1 2
print(individual_route(inpt_datf = datf_test,
                       col_target = "city",
                       id_col = "id",
                       untl_last = 3))
ACB AC CAC BA BAA

        1
             2
```

knn\_Rmach

knn\_Rmach

## **Description**

KNN algorythm, see example

#### Usage

```
knn_Rmach(train, test, k, col_vars_train = c(), col_vars_test = c(), class_col)
```

#### **Arguments**

train is a dataframe with the known individual and their variables and classification

columns

test is a dataframe with the new individuals with ich e do not know the class, only

the variables

```
k is the number of neighbours
```

```
col_vars_train
```

is a vector containing the column names or column numbers of the variables in train, if empty all column are considered as a variable apart from the last one that is considered as the classification column

```
col_vars_test
```

is a vector containing the column names or column numbers of the variables in test, if empty all column are considered as a variable

class\_col is the column name or column number of the classification column in train

## **Examples**

## **Description**

Allow to perform knn with cross validation for the optimal value of k neighbours used, see examples and parameters. The result outputed is a vector containing the ratio of correct label found divided by the total number of unique individuals in the current dataset where the training occurred. So, higher is better.

```
knn_Rmach_cross_validation_k(
  inpt_datf,
  train_prop,
  knn_v = c(),
  n_fold = 5,
  col_vars = c(),
  class_col
)
```

# Arguments

inpt_datf	is the input dataset as a ddataframe
train_prop	is the training proportion
knn_v	is a vector containing the values of k neighbours to test
n_fold	is the number of fold used for each value of $k$ , the higher this value is, he more accurate the result will be but the higher the amount of time it will takes
col_vars	is a vector containing the column names or numbers of the variables in the input dataframe
class_col	is the column names or number of the variable to predict in the input dataframe

## **Examples**

```
knn_Rmach_cross_validation_train knn_Rmach_cross_validation_train
```

# Description

Allow to perform knn with cross validation for the optimal value of k neighbours used, see examples and parameters. The result outputed is a vector containing the ratio of correct label found divided by the total number of individuals in the current dataset where the training occurred. So, higher is better.

```
knn_Rmach_cross_validation_train(
  inpt_datf,
  train_prop_v = c(),
  k,
  n_fold = 5,
  col_vars = c(),
  class_col
)
```

Im\_label\_generation 23

#### **Arguments**

inpt_datf	is the input dataset as a ddataframe
n_fold	is the number of fold used for each value of k, the higher this value is, he more accurate the result will be but the higher the amount of time it will takes
col_vars	is a vector containing the column names or numbers of the variables in the input dataframe
class_col	is the column names or number of the variable to predict in the input dataframe
train_prop	is the training proportion
knn_v	is a vector containing the values of k neighbours to test

## **Examples**

```
lm\_label\_generation \\ lm\_label\_generation
```

# Description

Allow to generate new individuals whose label are not present enough. It supposes that the variables and the label al have a linear relationship. This methods generates values of variables for new individuals based on a normal distribution whose mean is the value of the function found after a linear regression between a variable and the label, at the x value (label value). The standard deviation associated with the normal distribution is the local standard deviation with a given amount of neighbours. A neighbour is the set of individuals that share the same label. If the amount of neighbours exceeds the number of labels, so all labels will be considerd as a neighboor to calculate the local standard deviation.

```
lm_label_generation(inpt_datf, col_vars = c(), label_var, min_hmn, neighbrs)
```

## **Arguments**

inpt\_datf is the input dataframe col vars is a vector containing the column names or number of the variables label\_var is the column name or number of the label variable min hmn is the value from which a label is considered to appear enough times, so all individuals that have a label whose occurence is inferior will be cloned base on the method elaborated in the description of the function neighbrs is how many neighbours will be taken in count to calculate the local standard

deviation

```
datf <- iris
datf <- datf[-c(101:137),]</pre>
datf[, 5] <- as.character(datf[, 5])</pre>
datf[datf[, 5] == "setosa", 5] <- 1
datf[datf[, 5] == "versicolor", 5] <- 2
datf[datf[, 5] == "virginica", 5] <- 3
datf[, 5] <- as.numeric(datf[, 5])</pre>
rownames(datf) <- c(1:nrow(datf))</pre>
nrint (datf)
```

```
lm_label_generation2
```

 $lm\_label\_generation2$ 

# Description

Same as lm\_label\_generation but limits the new individuals to min\_hmn.

# Usage

```
lm_label_generation2(inpt_datf, col_vars = c(), label_var, min_hmn, neighbrs)
```

# Arguments

inpt_datf	is the input dataframe
col_vars	is a vector containing the column names or number of the variables
label_var	is the column name or number of the label variable
min_hmn	is the value from which a label is considered to appear enough times, so all individuals that have a label whose occurence is inferior will be cloned base on the method elaborated in the description of the function
neighbrs	is how many neighbours will be taken in count to calculate the local standard deviation

```
datf <- iris
datf <- datf[-c(101:137),]</pre>
datf[, 5] <- as.character(datf[, 5])</pre>
datf[datf[, 5] == "setosa", 5] <- 1</pre>
datf[datf[, 5] == "versicolor", 5] <- 2</pre>
datf[datf[, 5] == "virginica", 5] <- 3</pre>
datf[, 5] <- as.numeric(datf[, 5])</pre>
rownames(datf) <- c(1:nrow(datf))</pre>
print(datf)

multiple_groups multiple_groups
```

#### **Description**

Output all the possible combinations between elements within a vector for a group size, see examples

## Usage

```
multiple_groups(inpt_v = c(), group_size = 2)
```

## **Arguments**

```
inpt_v is the input vector
group_size is the group size
```

```
print(multiple_groups(inpt_v = c("Marc", "Sylvie", "Julien", "Christine", "Axel"), group_
 [1] "Marc-Sylvie"
                        "Marc-Julien"
                                           "Marc-Christine"
                                                              "Marc-Axel"

[1] "Marc-Sylvie-Julien-Christine-Axel"
```

36 poly\_model

poly\_model

Rmach poly\_model

#### **Description**

Take a datasets of x and y values and a function tha could fit all the data with the missing coefficients, and returns a list containing the coefficients that fit the best the data for a given function, as a vector for the first index, and at the second index, the actual sum of difference between each data point and the function at the same x values.

# Usage

```
poly_model(
   inpt_datf,
   degree,
   twk_val = NA,
   sensi_val = twk_val,
   coeff_v = NA,
   powers = NA,
   mth_symb = c("x"),
   numrtr_v = NA
)
```

#### **Arguments**

degree

twk\_val

sensi\_val

coeff\_v

powers

inpt_datf	is the input data as a dataframe, first column is the x values and the second is the
	v values

is how many coefficients will be involved (each coefficient multiplies either an x to the power of something, an exponential of something or a base something logarithm for a something value)

is the value used for finding the best coefficients, it is directly linked to the accuracy of the coefficients, see the description for more information. Defaults to (max(yval) - min(yval)) / n

is the value from which two variations of a coefficient brings a so small accuracy contribution that the algorythm does not continue to find better coefficients. For example, if i set sensi\_val = 0.001, so if coefficients alpha1 and beta1 brings a total difference between the function and the actual data of 10.8073 and then the algorythm find alpha2 and beta1 that brings a total difference equal to 10.8066, so the algorythm will stop running. But the coefficients returned will still be the best, that is alpha2 and beta1

is a vector containing the original coefficients for the function, so the closest those are from the best one, the fastest the algorythm will compute the best coefficients. The first value of coeff is always the constant.

is a vector containing the exponent, or related value to mth\_symb. powers can be a vector if those values are constants or it could be a list of vectors the length of observed individuals, if those values varies like in the examples. Notthat if you use variables in powers (list), each values of a vector from this list has to be at the exact same x coordinates of each observed individuals in the input dataframe. Ex: datf <- data.frame("x"=c(4, 4, 3, 2, 1, 1), "y"=c(1:6)), so vector(s) from

poly\_model 37

powers that contain varying value must be of length 4. Also, the values are not ascendly sorted, don't worry values are ascendly sorted under the hood, so fill your powers vectors in the intuitive ascendly way

mth\_symb

is a vector containing the elemnts linked to the coefficients from the second element. It can be x,  $e(\exp(x))$  or  $\log - X(\log(x)$ -base), and their reverse like 1/x. If the numerator varies the element should be entered like tis list/x, list/e or list/log-base. See numrtr\_v for the values related to list

numrtr\_v

is a vector containing the values for the numerator related to mth\_symb if on element is like this: list/x or list/e

## **Examples**

[[1]]

```
print(poly_model(inpt_datf=data.frame(mtcars$wt, mtcars$mpg), degree=2, coeff_v=c(32.5, -
